

Why CI(lognorm) recovery DROPS at low σ but is 100% at high σ (cmax=0.45)

Top: estimation story from grid JSON — failures sit at min $\sigma < 0.15$ where $\Delta AIC \approx 0$ and p_c is inestimable.

Bottom: behavioural predictions — at $\sigma \rightarrow 0$ the CI PSE curve collapses toward fusion + saturated posterior.

At low σ , $\Delta AIC \approx 0 \rightarrow p_c$ buys no LL,

p_c recovery: scattered when σ small,
tight when σ adequate

σ -a cmax=0.45: failures cluster at the LOWEST σ

AIC penalty flips to fusion

PSE vs conflict — very low $\sigma=0.03$ (σ -a floor)

PSE vs conflict — high $\sigma=0.50$ (σ -c)

mean posterior(common cause)
saturates hard when σ small
